# 1974 SHORT-SEASON COTTON VARIETY TESTS

By L. N. Namken, M. D. Heilman, R. G. Brown, and R. V. Cantu<sup>2</sup>

#### ABSTRACT

Twenty short-season cotton varieties (*Gossypium hirsutum* L.) were grown at Weslaco, Tex. Yield, micronaire, length uniformity, strength, growth and fruiting characteristics, and earliness are reported. Earliness was judged by four different measures.

#### INTRODUCTION

Interest in short-season management systems for improving cotton (Gossypium hirsutum L.) production efficiency has created a need to evaluate the performance of recently released early-maturing varieties and advanced strains under lower Rio Grande Valley conditions. These tests, performed at Weslaco, Tex., supplement regular cotton variety tests by obtaining more detailed information on earliness, fruiting characteristics, and plant growth. They also provide a direct comparison of the performance of conventional varieties with early-maturing varieties recently released or advanced strains about to be released.

This information will help cotton growers decide whether it would be advantageous to use the new varieties in a short-season management system. It will also help cotton breeders evaluate the performance of advanced early-maturing strains under southern Texas environmental conditions.

#### **METHODS**

The 1974 tests were conducted on a Hidalgo sandy clay loam at the Soil and Water Conservation District-Agricultural Research Service Research Farm, 5 miles north of Weslaco, Tex. A randomized complete-block design with 3 replications was used to accommodate 20 varieties and advanced strains. The entries were planted in a double-drill configuration with the two drills 8 inches apart on 40-inch centers (shaped beds) and irrigated on February 28.

<sup>1</sup>Soil scientist, Agricultural Research Service, U.S. Department of Agriculture, Weslaco, Tex. 78596.

Each plot was four rows wide and 40 feet long. Stands were thinned to 60,000 to 65,000 plants per acre on March 22. The plots were irrigated once in alternate furrows on June 4. Total rainfall from planting to defoliation (July 22, 144 days after planting) was 4.5 inches. Insecticide applications were based on recommendations provided by a pestmanagement scouting program. No fertilizer was applied.

In the tables reporting results, means not followed by the same letter are significantly different at the 0.05 probability level as indicated by Duncan's multiple-range test.

#### YIELD AND STAPLE CHARACTERISTICS

Twenty-five feet of the southern inside row of each plot was handpicked, with the first harvest on July 8 (130 days after planting). Subsequent harvests were on July 17, July 29, and August 13 to establish yield-maturity curves. The northern inside row of each plot was harvested on August 1 and August 13. Total lint yields (table 1) were obtained by averaging the yields from the two inside rows in each plot. The lint-quality measurements (tables 2-7) were made on samples from the August 1 harvest of the north inside row. Since growers usually mechanically harvest cotton at this maturity, the August 1 harvest, having been exposed to the weather for the same amount of time, should be similar in quality to mechanically harvested cotton. The lint-quality measurements (length, micronaire, uniformity, and strength) reported in tables 4-7 were made on 250-gram lint samples by the Texas Tech University Textile Research Center, Lubbock.

# PLANT GROWTH AND FRUITING

Fifteen randomly selected plants in the north inside row of each plot were flagged at the six-leaf stage. All plant-growth and fruit-load measurements, reported in tables 8–15, were made on these plants at various stages of the season except the dates of first square and first bloom (tables 8 and 9), which were recorded for each plot, using all four rows in the plot.

### EARLINESS OF CROP MATURITY

Four measures of earliness of crop maturity are reported in tables 16–20. The percentage of total yield harvested at some point during the boll-maturing stage of plant development (in these tests, percentage of total yield 130 days from planting) and mean maturity date are measures commonly used by plant breeders to evaluate earliness.

The production rate index was recently suggested by Bilbro and Quisenberry<sup>3</sup> as a means of expressing earliness that is yield related (i.e., amount produced per unit of time). Two varieties

might have approximately the same yield variety could produce its yield in a shorter but one time than the other; thus, it would have priod of production rate index and would be considered higher more efficient.

more efficient.

The fruit-set index, defined by Roark<sup>4</sup> as the ratio of the number of first fruiting sites on each fruiting of fruiting branches, expressed as a percentumber considered a measure of adaptability to a given enpercentage of shed at these sites (low fruit-set set on sites further out on the fruiting branches and thus delays the crop.

<sup>4</sup>Bruce Roark. 1972. The effects of shedding on maturity date and yield. (Abstract) Proc. Beltwide Cotton Prod. Res. Conf.,
